ABSTRACT
Processing a signal directly in the encrypted domain provides an elegant solution in application scenarios where valuable signals must be protected from a malicious processing device. In a previous paper we considered the implementation of the 1D Discrete Fourier Transform (DFT) in the encrypted domain, by using the homomorphic properties of the underlying cryptosystem. In this paper we extend our previous results by considering the application of the 2-dimensional DCT to encrypted images. The effect of the consecutive application of the DCT algorithm first by rows then by columns is considered, as well as the differences between the implementation of the direct DCT algorithm and its fast version. Particular attention is given to block-based DCT, with emphasis on the possibility of lowering the computational burden by parallel application of the encrypted domain DCT algorithm to different image blocks.

Index Terms— Discrete Cosine transforms, error analysis, homomorphic encryption, image encryption, signal processing in the encrypted domain

1. INTRODUCTION
The availability of signal processing modules that work directly on encrypted data would be of great help for applications where sensitive signals must be processed. In the image processing field, a recent example regards buyer-seller watermarking protocols [1] which prevent the seller from obtaining a plaintext of the watermarked image. In the encrypted domain (s.p.e.d.) is a new field of research aiming to protect the seller from a malicious processing device. In a previous paper we considered the similar problem of implementing a s.p.e.d. DCT which permits the parallel application of the DCT coefficients along rows and columns. Let us consider a signal that is represented by a sequence of pixels that belong to a finite alphabet. A convenient s.p.e.d. signal model will be proposed, allowing us to decide if they conceal the same value. This is fundamental, since encrypted values cannot be scaled or truncated by relying on the homomorphic properties and the fact that the DCT coefficients are public. However, this requires several issues to be solved. The first one is that we must represent the pixel values, the DCT coefficients, and the transformed values in the domain of the cryptosystem, i.e., as integers on a finite field/ring. Another problem is that encrypted values cannot be scaled or truncated by relying on homomorphic computations only. In general, for scaling the intermediate values of the computation we should allow two or more parties to interact [4]. However, since we would keep the s.p.e.d. DCT as simple as possible, it is preferable to avoid the use of interactive protocols. A final problem is that encrypting each pixel separately increases the size of the encrypted image and affects the complexity.

In this paper, we will provide solutions to the above issues. A convenient s.p.e.d. signal model will be proposed, allowing us to define both a s.p.e.d. DCT and a s.p.e.d. fast DCT and to extend them to the 2D case, by considering the consecutive application of the DCT first by rows then by columns. Moreover, we will propose a block-based s.p.e.d. DCT which permits the parallel application of the s.p.e.d. DCT algorithm to different image blocks, thus lowering both the bandwidth usage and the computational burden.

2. SIGNAL MODEL
We will describe the method assuming the signals are 1-D sequences. The extension to the 2-D case is straightforward by using separable processing along rows and columns. Let us consider a signal \( x(n) \in \mathbb{R}, n = 0, \ldots, M - 1 \). In the following, we will assume \( |x(n)| \leq 1 \). The scaled DCT of type II (DCT-II) of \( x(n) \) is defined as

\[
X(k) = \sum_{n=0}^{M-1} x(n) \cos \left( \frac{(2n + 1)k}{2M} \right), \quad k = 0, 1, \ldots, M - 1.
\]  

(2)

As in [2], the integer DCT is defined as

\[
S(k) = \sum_{n=0}^{M-1} C_M(n, k)s(n), \quad k = 0, \ldots, M - 1
\]  

(3)

where \( E[\cdot] \) and \( D[\cdot] \) denote the encryption and decryption operators. With such a cryptosystem it is indeed possible to add two encrypted values without first decrypting them and it is possible to multiply an encrypted value by a public integer value by repeatedly applying the operator \( \phi(\cdot, \cdot) \). Moreover, we will assume that the cryptosystem is probabilistic, that is, given two encrypted values it is not possible to decide if they conceal the same value. This is fundamental, since the alphabet to which the input pixels belong is usually limited. A widely known example of a cryptosystem fulfilling both the above requirements is the Paillier cryptosystem [3], for which the operator \( \phi(\cdot, \cdot) \) is a modular multiplication.

The DCT can be computed on the encrypted pixel values by relying on the homomorphic properties and the fact that the DCT coefficients are public. However, this requires several issues to be solved. The first one is that we must represent the pixel values, the DCT coefficients, and the transformed values in the domain of the cryptosystem, i.e., as integers on a finite field/ring. Another problem is that encrypted values cannot be scaled or truncated by relying on homomorphic computations only. In general, for scaling the intermediate values of the computation we should allow two or more parties to interact [4]. However, since we would keep the s.p.e.d. DCT as simple as possible, it is preferable to avoid the use of interactive protocols. A final problem is that encrypting each pixel separately increases the size of the encrypted image and affects the complexity.

In this paper, we will provide solutions to the above issues. A convenient s.p.e.d. signal model will be proposed, allowing us to define both a s.p.e.d. DCT and a s.p.e.d. fast DCT and to extend them to the 2D case, by considering the consecutive application of the DCT first by rows then by columns. Moreover, we will propose a block-based s.p.e.d. DCT which permits the parallel application of the s.p.e.d. DCT algorithm to different image blocks, thus lowering both the bandwidth usage and the computational burden.
where \( s(n) = [Q_1 x(n)] \), \( C_M(n, k) = [Q_2 \cos \frac{\pi (2n+1)k}{2M}] \), \( \lceil \cdot \rceil \) is the rounding function and \( Q_1 \) and \( Q_2 \) are suitable scaling factors.

Since all computations are between integers and there is no scaling, the expression above can be evaluated in the encrypted domain by relying on the homomorphic properties. If the inputs are encrypted with the Paillier cryptosystem, the s.p.e.d. DCT is

\[
E[S(k)] = \prod_{n=0}^{M-1} E[s(n)]^{C_M(n, k)}, \quad k = 0, \ldots, M - 1
\]

where all computations are done modulo \( N^2 \) [3].

### 3. S.P.E.D. DCT

The computation of the DCT using (3) requires two problems to be tackled with. The first one is that there will be a scaling factor between \( S(k) \) and \( X(k) \). The second one is that, if the cryptosystem encrypts integers modulo \( N \), one must ensure that there is a one-to-one mapping between \( S(k) \) and \( X(k) \) mod \( N \). A solution is to find an upper bound on \( S(k) \) such that \( |S(k)| \leq Q_S \), and verify that \( N > 2Q_S \). We will show that \( S(k) \) can be expressed in general as

\[
S(k) = K X(k) + \epsilon_S(k)
\]

where \( K \) is a suitable scaling factor and \( \epsilon_S(k) \) models the quantization error. Based on the above equation, the desired DCT output can be estimated as \( X(k) = S(k)/K \), and the upper bound is

\[
Q_S = MK + \epsilon_{S,U}
\]

where \( \epsilon_{S,U} \) is an upper bound on \( \epsilon_S(k) \). The value of both \( K \) and \( \epsilon_{S,U} \) will depend on the particular implementation of the DCT.

#### 3.1. Direct Computation

Let us express \( s(n) = Q_1 x(n) + \epsilon_s(n) \) and \( C_M(n, k) = Q_2 \cos \frac{\pi (2n+1)k}{2M} + \epsilon_C(n, k) \). If the DCT is directly computed by applying (3), then we have

\[
S(k) = Q_1 X(k) + \epsilon_S(k)
\]

where \( \epsilon_S(k) = \sum_{n=0}^{M-1} [Q_1 x(n) \epsilon_c(n, k) + Q_2 \epsilon_s(n) \cos \frac{\pi (2n+1)k}{2M} + \epsilon_c(n) \epsilon_C(n, k)] \). The scaling factor is \( K_D = Q_1 Q_2 \). As to the quantization error, we obtain the following upper bound

\[
|\epsilon_S(k)| \leq M \left( \frac{Q_1}{2} + \frac{Q_2}{2} + \frac{1}{4} \right) = \epsilon_{S,U}
\]

from which \( Q_{S,D} = MQ_1 Q_2 + \epsilon_{S,U,D} \).

#### 3.2. Fast DCT

In order to obtain a s.p.e.d. version of the fast DCT, we will refer to the recursive matrix representation in [5]. Given \( [T_M]_{nk} = \cos \frac{\pi n k}{2M} \), we have

\[
T_M = A_M \begin{bmatrix} \frac{I_{M/2}}{2} & 0 & 0 \\ 0 & \frac{L_{M/2}}{2} & 0 \\ 0 & 0 & T_{M/2} \end{bmatrix} \begin{bmatrix} I_{M/2} & 0 & 0 \\ 0 & L_{M/2} & 0 \\ 0 & 0 & T_{M/2} \end{bmatrix}
\]

\[
= A_M \begin{bmatrix} T_{M/2} & 0 & 0 \\ 0 & T_{M/2} & 0 \\ 0 & 0 & D_{M/2} \end{bmatrix} B_M
\]

where \( D_{M/2} = \text{diag} \{ \cos \frac{\pi}{2M}, \cos \frac{3\pi}{2M}, \ldots, \cos \frac{(M-1)\pi}{2M} \} \), and the upper bound is

\[
J_M = \text{obtained by the } M \times M \text{ identity matrix by reversing the column order and } P_M \text{ is a suitable permutation matrix (see [5]).}
\]

Since the only non integer matrix in (9) is \( D_{M/2} \), the corresponding s.p.e.d. structure can be recursively defined as

\[
C_M = A_M \begin{bmatrix} C_{M/2} & 0 & 0 \\ 0 & C_{M/2} & 0 \\ 0 & 0 & Q_2 I_{M/2} \end{bmatrix} B_M
\]

(10)

where we define \( \tilde{D}_{M/2} = [Q_2 D_{M/2}] \).

As to the upper bound analysis, let us consider the \( n \)-th stage of the recursion and express the quantized matrices as \( D_{2m} = Q_2 D_{2m} + E_D^{(m)} \) and \( C_{2m} = K^{(m)} T_{2m} + E_T^{(m)} \). Then, we can rewrite (10) as

\[
C_{2m+1} = A_{2m+1} \begin{bmatrix} K^{(m)} T_{2m} + E_T^{(m)} & 0 \\ 0 & K^{(m)} T_{2m} + E_T^{(m)} \end{bmatrix}
\]

\[
\times \begin{bmatrix} Q_2 I_{2m} & 0 \\ 0 & Q_2 D_{2m} + E_D^{(m)} \end{bmatrix} B_{2m+1}
\]

\[
= K^{(m)} Q_2 T_{2m+1}
\]

\[
+ A_{2m+1} \begin{bmatrix} K^{(m)} T_{2m} & 0 \\ 0 & K^{(m)} T_{2m} \end{bmatrix}
\]

\[
\times \begin{bmatrix} E_{T}^{(m)} & 0 \\ 0 & E_D^{(m)} \end{bmatrix}
\]

\[
+ E_T^{(m)}
\]

\[
+ \begin{bmatrix} Q_2 I_{2m} & 0 \\ 0 & Q_2 D_{2m} \end{bmatrix} B_{2m+1}
\]

\[
= K^{(m+1)} T_{2m+1} + E_T^{(m+1)}
\]

(11)

From the above equation, we have both a recursive relation on the scaling factor and a recursive relation on the quantization error. Let us consider the vector of quantized inputs \( \mathbf{s} = [s(0), s(1), \ldots, s(M-1)]^T \). With a notational similar to the scalar case, we can express \( s = Q_1 \mathbf{x} + \mathbf{e}_s \), where \( \mathbf{x} \) is a vector containing the input values and \( \mathbf{e}_s \) is a vector of quantization errors. Hence, the s.p.e.d. fast DCT is given by

\[
C_{2^m} \mathbf{s} = K^{(m)} Q_1 \mathbf{T}_{2^m} \mathbf{x} + K^{(m)} \mathbf{T}_{2^m} \mathbf{e}_s + E_T^{(m)} Q_1 \mathbf{x} + E_T^{(m)} \mathbf{e}_s.
\]

(12)

As to the scaling factor, we have \( K_T = K^{(m)} Q_1 \). Since \( K_T^{(m)} = 1 \), it is easy to derive the final scaling factor as \( K_T = Q_S^2 Q_1 \). As to the quantization error, we have \( |\epsilon_S(k)| \leq M K_T^{(m)} / 2 + (Q_1 + 1/2) \| \mathbf{E}_T^{(m)} \| \infty \), where \( \| \cdot \| \infty \) denotes the maximum absolute row sum norm of a matrix. Based on (11), we can give an equivalent recursive relation on \( \| \mathbf{E}_T^{(m)} \| \infty \) as

\[
\| \mathbf{E}_T^{(m+1)} \| \infty \leq (2^{m+1} + 1) \left( 2^m K^{(m)} + \| \mathbf{E}_T^{(m)} \| \infty (2Q_2 + 1) \right)
\]

(13)
where we used \( \|A_{m+1}\|_\infty = 2^{m+1} - 1 \), \( \|B_{m+1}\|_\infty = 2^m \), \( \|K^{(m)}T_{2^m}\|_\infty = 2^m K^{(m)} \), and \( \|E^{(m)}_D\|_\infty = 1/2 \). At the start of the recursion we have \( \|E^{(0)}_B\|_\infty = 0 \), since \( T_1 = 1 \) and there is no quantization error. Hence, an upper bound on \( \|E^{(m)}_D\|_\infty \) can be derived as

\[
\|E^{(m)}_D\|_\infty \leq \sum_{k=0}^{\nu-1} (2Q_2 + 1)^k 2^{r-k} Q_2^{r-k} \prod_{r=-k}^{\nu} (2^{r+1} - 1) = \epsilon_{E,U} \tag{14}
\]

from which we derive the upper bound on the quantization error as

\[
|\epsilon_S(k)| \leq \frac{M Q_2^2}{2} + \left( Q_1 + \frac{1}{2} \right) \epsilon_{E,U} = \epsilon_{S,U,F} \tag{15}
\]

Finally, the upper bound on \( S(k) \) is \( Q_S F_2 + \epsilon_{S,U,F} \).

### 4. Extension to 2D-DCT

In the case of separable processing of the rows and the columns of an image, the expressions derived in the preceding section can be extended to the 2D case in an easy way. Let us assume that the 2D-DCT processes first the rows and then the columns. After the processing of the rows, the input to the next DCT will be expressed as in (5). Hence, the scaling factor can be obtained by substituting \( Q_1 \) with \( K \) whereas the upper bound on the quantization error can be derived by noting that \( |S(k)| \leq MK + \epsilon_{S,U,F} \).

In the case of the direct DCT implementation, this leads to

\[
K^{2D}_{S,D} = Q_2 K_D = Q_2^2 Q_1 \tag{16}
\]

\[
\epsilon_{S,U,D,D} = M \left( \frac{MK_D}{2} + Q_2 \epsilon_{S,U,D} + \epsilon_{S,U,D} \right) \tag{17}
\]

\[
Q^{2D}_{S,D} = M^2 K^{2D}_{D} + \epsilon_{S,U,D} \tag{18}
\]

whereas in the case of the fast DCT we obtain

\[
K^{2D}_{F} = Q_2^2 K_F = Q_2^2 Q_1 \tag{19}
\]

\[
\epsilon_{S,U,F,D} = M Q_2 \epsilon_{S,U,F} + (MK_F + \epsilon_{S,U,F}) \epsilon_{E,U} \tag{20}
\]

\[
Q^{2D}_{S,F} = M^2 K^{2D}_{F} + \epsilon_{S,U,F} \tag{21}
\]

### 5. S.P.E.D. Block-Based DCT

Several image processing algorithms, instead of applying the DCT to the whole image, subdivide it into equal sized (usually square) blocks and compute the DCT of each block. The size of such blocks is usually quite small: typically 8 \( \times \) 8 blocks or 16 \( \times \) 16 blocks are used in most of the applications.

From the s.p.e.d. perspective, this suggests two things: first, even if rescaling is not applied, in the case of a block based s.p.e.d. DCT the maximum value of the DCT outputs will not be very high. Since the modulus of practical cryptosystems has a size of one thousand bits or more, it is expected that the outputs of the s.p.e.d. block-based DCT will be far for exploiting the full bandwidth of the modulus. Second, each block undergoes exactly the same processing. Hence, this permits a parallel processing of several blocks by simply packing the pixels having the same position within the blocks in a single word.

In order to exploit the above ideas, we propose a s.p.e.d. block DCT (BDCT) based on a different representation of the input pixels. Let us consider \( R \) distinct blocks of an image. For the sake of simplicity, we can assume the blocks as one-dimensional, having size \( M \), since the extension to the 2D case is straightforward using separable processing. Let us define the block bandwidth as \( B = \lfloor \sqrt{N} \rfloor \). Moreover, let us assume that the input pixel values have been quantized as in Section 2. The pixels having the same position within each block are packed in a single word as

\[
s_p(n) = \sum_{i=0}^{R-1} s_i(n) + Q_1 B^i \tag{22}
\]

where \( s_i(n) \) denotes the pixel having position \( n \) within the \( i \)th block. If \( s_i(n) + Q_i < B \), \( i = 0, 1, \ldots, R - 1 \) then the packed word can be thought as a base \( B \) positive number whose digits are given by \( s_i(n) + Q_1 \). Note that the offset \( Q_1 \) is required in order to have positive digits. The above condition is surely satisfied if \( B > 2Q_1 \). Moreover, thanks to the definition of \( B \) we have \( |s_p(n)| < N \). Hence, given the modulo \( N \) representation of \( s_p(n) \), one can always extract the correct values of \( s_i(n) \), \( i = 0, 1, \ldots, R - 1 \) (That is, it is possible to define a one-to-one mapping between \( s_p(n) \) and \( \{s_0(n), s_1(n), \ldots, s_{R-1}(n)\} \).

The s.p.e.d. BDCT is defined as

\[
S_p(k) = \sum_{n=0}^{M-1} s_p(n) C(n,k) - \Omega(k) \tag{23}
\]

where

\[
\Omega(k) = \sum_{i=0}^{R-1} \left[ Q_1 \sum_{n=0}^{M-1} C(n,k) - Q_S \right] B^i. \tag{24}
\]

**Theorem 1** The BDCT satisfies

\[
S_p(k) = \sum_{i=0}^{R-1} |S_i(k) + Q_S| B^i \tag{25}
\]

where \( S_i(k) \) is the s.p.e.d. DCT of \( s_i(n) \). Moreover, if \( B > 2Q_S \) then the BDCT is correctly defined modulo \( N \).

**Proof:** let us consider the following equalities

\[
\sum_{n=0}^{M-1} s_p(n) C(n,k) = \sum_{n=0}^{M-1} s_i(n) + Q_1 B^i C(n,k)
\]

\[
= \sum_{i=0}^{R-1} \sum_{n=0}^{M-1} s_i(n) + Q_1 C(n,k) B^i \tag{26}
\]

Then, by subtracting (24) from the last equality (25) is readily proved. Moreover, if \( B > 2Q_S \) then \( |S_p(k)| < N \), so that it is possible to recover \( S_i(k) \), \( i = 0, 1, \ldots, R - 1 \) from \( S_p(k) \).

By using the BDCT we are able to process \( R \) blocks using a single s.p.e.d. DCT. Therefore, the complexity of the s.p.e.d. BDCT is reduced by a factor \( R \) with respect to that of the s.p.e.d. DCT. Moreover, also the bandwidth usage is reduced by the same factor, since we pack \( R \) pixels into a single ciphertext. However, note that extracting a single encrypted coefficient from the packed word requires some interactive protocol.

Finally, we would like to point out that the fast DCT algorithm can be used for the BDCT as well. The fast BDCT algorithm can be described by the following steps: 1) compute the fast DCT of the packed signal \( s_p(n) \); 2) compute the offset \( \Omega(k) \) by applying the
fast DCT to a vector containing all \( Q \)'s and by using \( Q_{S,F} \) in (24); compute the fast BDCT by subtracting \( \Omega(k) \) found in (2) from the result of 1). In order to verify that the above algorithm is correct, it suffices to substitute \( C(n,k) \) in (23)+(24) with the \( (n,k) \) element of the matrix \( C_M \) as defined in (10).

6. NUMERICAL EXAMPLES

We will consider the application of the s.p.e.d. 2D-DCT and 2D-BDCT to square \( M \times M \) 8-bit greyscale images. The quantization scaling factor can be assumed as \( Q_1 = 128 \). As to \( Q_2 \), we will assume that the cosine values are quantized so as not to exceed the quantization error of the corresponding plaintext implementation. Three plaintext implementations are considered: 1) 16-bit fixed point (XP); 2) single precision floating point (FP1); 3) double precision floating point (FP2). In the first case, we can assume \( Q_2 = 2^{15} \). In the floating point case, since the smallest magnitude of a cosine value is equal to \( \frac{\sin(\pi/2M)}{2M} \), we need \( Q_2 > 2^f/\sin(\pi/2M) \), where \( f \) is the number of bits of the fractional part of the floating point representation. For the sake of simplicity, we will assume \( M \leq 4096 \), so that we can choose \( Q_2 = 2^{36} \) (FP1) and \( Q_2 = 2^{65} \) (FP2).

Since the values of \( Q_S \) in (18)-(21) can be huge, in the case of the full frame DCT we will consider an upper bound on the number of bits required in order to correctly represent the DCT outputs. If we assume \( Q_{S,Z}^D < 2M^2 K_{Z}^D \), this can be expressed as

\[
\log_2 Q_{S,Z}^D + 1 < 2\nu + \log_2 K_{Z}^D + 2 = \nu_{U,Z} \tag{27}
\]

where \( \nu = \log_2 M \) and \( Z = \{D,F\} \). Note that if \( \log_2 N > \nu_{U,Z} \), it follows that \( N > 2Q_{S,Z} \). In Table 1, we give some upper bounds considering different values of \( M \) and \( Q_2 \). Highlighted in bold are the cases which can not be implemented relying on a 1024-bit modulus, which is a standard in several cryptographic applications. As can be seen, except for the case of FP2, a full frame s.p.e.d. DCT can be always implemented relying on a standard modulus.

As to the s.p.e.d. 2D-BDCT, we consider an estimate of the number of pixels that can be safely packed into a single word. A safe implementation requires \( B = [2Q_{S,Z}] \). Since we must have \( B < \sqrt{N} \), this leads to

\[
R_{\max} = \left\lfloor \frac{\log_2 N}{\log_2 [2Q_{S,Z}]} \right\rfloor \approx \left\lfloor \frac{\log_2 N}{\log_2 Q_{S,Z}} \right\rfloor = R_{U,Z} \tag{28}
\]

In Table 1, we give some values of \( R_{U,Z} \) considering \( 8 \times 8 \) and \( 16 \times 16 \) BDCTs and different precisions. The results demonstrate that the s.p.e.d. BDCT approach can effectively reduce both the bandwidth requirements and the complexity, especially for the fixed point case. It is worth noting that a direct implementation allows us to increase \( R_{U,Z} \) up to three times with respect to the fast BDCT. Since the BDCT usually works with small sized blocks, the complexity of the direct implementation will not be much higher than that of the fast implementation. For instance, an \( 8 \times 8 \) fast DCT requires 12 multiplications [6] versus the 64 multiplications of a naïve direct DCT. Hence, there can be cases in which it is preferable to employ a direct s.p.e.d. BDCT, since this will reduce the bandwidth usage at a small cost in complexity.

7. CONCLUDING REMARKS

We have considered the implementation of the DCT on an encrypted image relying on the homomorphic properties of the underlying cryptosystem. It has been shown how the maximum allowable DCT size depends on the modulus of the cryptosystem, on the chosen DCT implementation, and on the required precision. We have also proposed a s.p.e.d. block DCT which is based on the packing of several pixels into a single encrypted word, thus permitting the parallel application of the s.p.e.d. DCT algorithm to different image blocks. The results demonstrate that the proposed s.p.e.d. BDCT can effectively lower both the bandwidth usage and the computational burden. Our approach gives useful design criteria for the implementation of s.p.e.d. image processing modules and suggests other issues to be addressed in future research on s.p.e.d. topics, for example the tradeoff between bandwidth usage and complexity.
